It is generally agreed that striking a balance between resuming economic and social activities and keeping the effective reproductive number (R0) below 1 using nonpharmaceutical interventions is an important goal until and even after effective vaccines become available. Therefore, the need remains to understand how the virus is transmitted in order to identify high-risk environments and activities that disproportionately contribute to its spread so that effective preventative measures could be put in place. Contact tracing and household studies, in particular, provide robust evidence about the parameters of transmission. In this Viewpoint, we discuss the available evidence from large-scale, well-conducted contact-tracing studies from across the world and argue that severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) transmission dynamics should inform policy decisions about mitigation strategies for targeted interventions according to the needs of the society by directing attention to the settings, activities, and socioeconomic factors associated with the highest risks of transmission.

Keywords. COVID-19; coronavirus; SARS-CoV-2; novel coronavirus; transmission.

Since coronavirus disease 2019 (COVID-19) was first described in December 2019, we have witnessed widespread implementation of local and national restrictions in many areas of the world and social, health, and economic devastation due to direct and indirect impact of the pandemic. It is generally agreed that striking a balance between resuming economic and social activities and keeping the effective reproductive number (R0) below 1 using nonpharmaceutical interventions is an important goal until and even after effective vaccines become available. Achieving this balance requires an understanding of how the virus is spread. There is also a need to identify the structural factors that contribute to transmission, a particular concern considering the already stark health disparities driven by socioeconomic and racial/ethnic inequities in our societies.

An understanding of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) transmission dynamics can inform policy decisions by directing attention to the settings and activities that confer the highest risk of transmission and understanding of the intersection between poverty, household crowding, and COVID-19. This understanding will allow policymakers and public health practitioners to shape the best strategy and preventative measures and inform the public about transmission risk. Epidemiological investigations including contact-tracing studies and outbreak investigations conducted so far across the world already provide crucial information about the probability of infection in close contacts and various environments. We argue that health authorities should use the large-scale, well-conducted contact-tracing studies and observations from across the world to date in their risk assessment and mitigation strategies. This article summarizes current knowledge about transmission dynamics and discusses recommendations that could prevent infections by focusing on factors associated with risk of transmission.

FACTORS INFLUENCING TRANSMISSION DYNAMICS

Emerging data suggest that risk of transmission depends on several factors, including contact pattern, host-related infectivity/susceptibility pattern, environment, and socioeconomic factors (Figure 1). We will discuss the emerging evidence relating to each of these aspects of transmission.

Contact Pattern

Contact-tracing studies provide early evidence that sustained close contact drives the majority of infections and clusters. For instance, living with the case, family/friend gatherings, dining, or traveling on public transport were found to have a higher risk for transmission than market shopping or brief (<10 minutes) community encounters [1–3]. While people are more likely to recall and disclose close and household contacts, and it is easier for tracers to identify the source, household studies provide important information about the contact patterns and activities...
associated with higher attack rates. Close contacts with the highest risk of transmission are typically friends, household members, and extended family, with a secondary attack rate that ranges from 4% to 35% [1, 4–8]. In the same household, higher attack rates are observed among spouses compared with the rest of the household [8]. A systematic review including 5 studies based on relationship demonstrated that household SAR (secondary attack rate) to spouses (43.4%; 95% confidence interval [CI], 27.1–59.6%) was significantly higher than to other relationships (18.3%; 95% CI, 10.4–26.2%) [8]. Similar results were observed in the USS Theodora Roosevelt outbreak in which those sharing the same sleeping space had a higher risk of being infected [9]. In addition, the attack rate has shown to be higher when the index case is isolated in the same room with the rest of the household or when the household members have daily close contact with the index case [10, 11]. Transmission is significantly reduced when the index case is isolated away from the family, or preventative measures such as social distancing, hand hygiene, disinfection, and use of face masks at home are applied [10, 11]. In a study of an outbreak in the largest meat-processing plant in Germany, while the universal point of potential contact among all cases was the workplace, positive rates were statistically significant for a single shared apartment, shared bedroom, and associated carpool [12]. These findings suggest that sleeping in the same room or sharing the same sleeping space and increased contact frequency constitute a high risk of transmission.

Large clusters have been observed in family, friend, and work-colleague gatherings including weddings and birthday parties [13, 14]. Other examples include gatherings in pubs, church services, and close business meetings [14–17]. These findings suggest that group activities pose a higher risk of transmission. In non–household contact-tracing studies, dining together or engaging in group activities such as board games have been found to be a high risk for transmission as well [18]. In the same household, frequent daily contact with the index case and dining in close proximity have been associated with increased attack rates [10, 11].

Large, long-term-care facilities such as nursing homes and homeless shelters have seen increased rates of infection, in part because of patterns of contact among staff and residents. In nursing home outbreak investigations from the Netherlands, Boston, and London, multiple viral genomes were identified, suggesting multiple introductions to the facility leading to infections among residents [19–21]. In an investigation of 17 nursing homes that implemented voluntary staff confinement with residents, including 794 staff members and 1250 residents...
in France, staff confining themselves to a single facility for a
weeklong period was associated with decreased outbreaks in
these facilities [22].

These findings emphasize that contact patterns, including the
duration of contact, contact frequency, proximity to index case,
and types of activities, influence transmission risk, highlighting
the need for tailored prevention strategies for different settings.

Host Factors

Contact tracing and outbreak investigations suggest that many
people with SARS-CoV-2 either do not contribute to onward
transmission or have minimal potential to do so [6, 17], and
a large number of secondary cases are often caused by a small
number of infected patients. While this may also be due to con-
tact pattern and environmental factors, host factors strongly in-
fluence this variation; individual variation in infectiousness is
an expected feature of superspreading events.

Timing of the contact with an index case is key in transmis-
sion dynamics as it relates to the infectiousness of the index case.
In a systematic review of studies published up to 6 June 2020,
we found that viral load peaks early in the disease course, with
the highest viral loads observed from symptom onset to day 5,
indicating a high level of infectiousness during this period [23]
(Figure 2). Supporting these findings, transmission events are
estimated to occur in a short window, likely a few days prior to
and following symptom onset [4, 23]. For example, a contact-
tracing study that followed up 2761 contacts of 100 confirmed
COVID-19 cases demonstrated that infection risk was higher
if the exposure occurred within the first 5 days after symptom
onset, with no secondary cases documented after this point [4].
This understanding indicates that viral dose plays an important
role in transmission dynamics. In contrast, higher viral loads in
severe acute respiratory syndrome coronavirus (SARS-CoV-1)
and Middle East respiratory syndrome coronavirus (MERS-
CoV) were identified in the second week after symptom onset,
suggesting that patients had viral load peak after hospitalization
[23]. Therefore, early viral load peak also explains efficient com-
community SARS-CoV-2 spread in contrast to SARS-CoV-1 and
MERS-CoV, during which community spread was put under con-
tral; however, nosocomial spread was an important feature of
the outbreaks. In contrast, during COVID-19, only a small
number of hospital-based outbreaks have been reported so far,
which may be due to a downturn in viral load levels later in the
disease course [23, 24].

Symptoms and severity of illness appear to influence trans-
mission dynamics as well. People with symptoms appear to have
a higher secondary attack rate compared with presymptomatic
and asymptomatic index cases (those who develop no symptoms

severe acute respiratory syndrome coronavirus 2.
cases observed in the United States have all been associated with positive [16]. Although it is much harder to observe large homeless shelter in Boston, 36% of those tested were positive for SARS-CoV-2 [20]. Among 408 individuals residing at a large homeless shelter, a high proportion of residents (39.8%) and staff (20.9%) who tested positive for SARS-CoV-2 [20]. Among 408 individuals residing at a large homeless shelter in Boston, 36% of those tested were found to be positive [16]. Although it is much harder to obtain data from incarcerated populations, the largest clusters of cases observed in the United States have all been associated with prisons or jails, suggesting a high attack rate in these institutional settings [29]. Social distancing is the opposite of incarceration, and overcrowding, poor sanitation and ventilation, and inadequate healthcare contribute to the disproportionate rates of infections seen in prisons and jails, which demonstrates the larger pattern of the health disparities in our societies.

Socioeconomic Factors and Racial/Ethnic Disparities
Global figures suggest that there is a strong association between socioeconomic deprivation, race/ethnicity, and a higher risk of infection and death from COVID-19 [30, 31]. People facing the greatest socioeconomic deprivation experience a higher risk of household and occupational exposure to SARS-CoV-2, and existing poor health leads to more severe outcomes if infected [32]. People with lower-paid and public-facing occupations are often classified as essential workers who must work outside the home and may travel to work on public transport. Indeed, in New York City, higher cumulative infection rates were observed in neighborhoods that continued to engage in mobility behaviors consistent with commuting for work [33]. These occupations often involve greater social mixing and greater exposure risk due to prolonged working hours, resulting in reduced ability to practice social distancing among low-income families [34]. In addition, households in socioeconomically deprived areas are more likely to be overcrowded, increasing the risk of transmission within the household. Black, Hispanic, and other marginalized, racial/ethnic, and migrant groups have also been shown to be at greater risk of infection, severe disease, and death from COVID-19 [31, 35–37]. These increased risks are also likely due to socioeconomic conditions that increase the risk of transmission, inequitable access to adequate healthcare, and higher rates of comorbidities due to adverse living and working conditions and structural racism. It is not surprising that the largest outbreaks are observed in meat-packing plants, and most commonly exposed occupations include nurses, taxi and bus drivers, and factory workers [31]. These disparities also shape the strong geographic heterogeneities observed in the burden of cases and deaths—for example, across the United States and the United Kingdom [31, 38]. These findings support the hypothesis that the COVID-19 pandemic is strongly shaped by structural inequities that drive household and occupational risks, emphasizing the need to tailor effective control and recovery measures for these disadvantaged communities proportionate to their greater needs and vulnerabilities.

Large Clusters and Superspreading Events
Clusters have become a prominent characteristic of SARS-CoV-2, which distinguishes it from seasonal influenza [14, 17]. This emphasizes that large clusters and superspreading events may be the driver of the majority of infections, just as they were for SARS-CoV-1 in 2002–2003 [39, 40]. For instance, during the 2003 SARS-CoV-1 outbreak, over 70% of infections were linked to gatherings, such as those in nursing homes, homeless shelters, prisons, and also workplaces including meat-packing plants and factories, where many people spend several hours working together, dining and sharing communal spaces [12, 14].
to superspreading events in Hong Kong and Singapore [39]. Hallmarks for superspreading events include a combination of factors, typically a highly infectious individual(s) gathered with other individuals in enclosed and crowded environments [14, 17]. There have been several superspreading events reported so far. For example, an outbreak investigation from China identified that 24 out of 67 passengers were infected during a 50-minute return bus journey, which was linked to an index case who was symptomatic the day before the trip. In contrast, during the event, only 6 people were infected, all of whom were in close contact with the same index case [41]. In Washington State, a mildly symptomatic index case attended a choir practice (the practice was 2.5 hours), and out of 61 persons, 32 confirmed and 20 probable secondary COVID-19 cases occurred with an attack rate of 53.3% to 86.7% [42]. While these superspreading events occur, the frequency of these events and whether they are caused by a single index case are unclear. The modeling suggests that several independent introductions might be needed before a COVID-19 outbreak eventually takes off, meaning often these large outbreaks occur when multiple infected persons are introduced to the environment, as shown in the nursing home investigation [43]. Other large outbreaks are reported in night clubs, karaoke bars, and pubs [14, 17], which may be related to crowding, leading to multiple introductions into the same setting as seen in nursing home investigations. These findings and observations suggest that contact-tracing investigations need to be combined with phylogenetic analysis to understand the settings and activities most likely to yield a superspreading event to inform preventative measures.

RECOMMENDATIONS

Increased risk of transmission in deprived areas and among people in low-paid jobs suggests that poverty and household crowding need to be addressed with interventions that go beyond guidance on social distancing, hand hygiene, and mask use. Previous research suggests that, although social distancing during the 2009 H1N1 swine flu pandemic was effective in reducing infections, this effect was most pronounced in households with greater socioeconomic advantage. Similar findings are emerging for COVID-19, with the ability to practice social distancing strongly differentiated by county and household income [34]. The disproportionate impact of COVID-19 on households living in poverty and the racial and ethnic disparities observed in many countries emphasize the need to urgently address these inequities that directly impact health outcomes. This includes social and income protection and support to ensure low-paid, nonsalaried, and zero-hours contract workers can afford to follow isolation and quarantine recommendations; provision of protective equipment for workplaces and community settings; appropriate return-to-work guidelines; and testing and opportunities for isolation outside of the home to protect those still at work.

Second, knowing which contacts and settings confer the highest risk for transmission can help direct contact-tracing and testing efforts to increase the efficiency of mitigation strategies. Early viral load peak in the disease course indicates that preventing onward transmission requires immediate self-isolation with symptom onset, prompt testing, and results with a 24- to 48-hour turnaround time, and robust contact tracing. In many countries, people with symptoms access testing late in the disease course, by which time they may have had multiple contacts while in the most infectious period. While self-isolation with symptoms is crucial, 75% of those with symptoms and their contacts in the United Kingdom reported not fully self-isolating [44]. While presymptomatic transmission likely contributes to a fraction of onward transmission, over half of transmission is caused by those with symptoms, especially in the first few days after symptom onset. These findings suggest that messages should prioritize isolation practice, and policies should include supported isolation and quarantine.

Third, policymakers and health experts can help the public differentiate between lower-risk and higher-risk activities and environments and public health messages could convey a spectrum of risk to the public to support engagement in alternatives for safer interaction, such as in outdoor settings. Without clear public health communication about risk, individuals may fixate on unlikely sources of transmission—such as outdoor activities—while undervaluing higher-risk settings, such as family and friend gatherings and indoor settings. Enhancing community awareness about risk can also encourage symptomatic persons and contacts of ill persons to isolate or self-quarantine to prevent ongoing transmission.

Finally, because crowded indoor spaces and gatherings likely will continue to be the driver of transmission, public health strategies will be needed to mitigate transmission in these settings (eg, nursing homes, prisons and jails, shelters, and meatpacking plants), such as personal protective equipment and routine testing to identify infected individuals early in the disease course. As part of the pandemic response we may need to consider fundamentally redesigning these settings, including improved ventilation, just as improved sanitation was a response to cholera. Such strategies should be adopted in settings where large outbreaks and superspreading events have been identified by contact-tracing studies.

While modeling studies and computer simulations could contribute to our understanding of transmission dynamics and aerodynamics of droplets, contact-tracing studies provide real-life transmission dynamics and individual and structural factors associated with SARS-CoV-2 transmission, which are essential to shape our public health plans, mitigate superspreading events,
and control the current pandemic. Further understanding of transmission dynamics is also critical to developing policy recommendations for reopening businesses, primary and secondary schools, and universities.
